(Dated: July 6, 2012)

We present a modification of Matrix Product State time evolution to simulate the propagation of signal fronts on infinite one-dimensional systems. We restrict the calculation to a window moving along with a signal, which by the Lieb-Robinson bound is contained within a light cone. Signal fronts can be studied unperturbed for much longer times than on finite systems. Entanglement inside the window is naturally small, greatly lowering computational effort. We calculate the time evolution of the transverse field Ising (TFI) model and of the XXZ spin-half antiferromagnet after local quantum quenches. In both models, we observe distinct magnetization plateaus. In the TFI model, their dynamical scaling follows power laws to high precision.

Propagation of signals in one-dimensional (1D) strongly interacting systems has been of longstanding general interest in both condensed matter and quantum-computational physics. The phenomenon provides a basis for coherent information transfer via quantum wires. A signal can be created, e.g., as a local excitation from a stationary state, or as a domain wall or a topological excitation [1, 2]. In recent years, the nonequilibrium time evolution of such signals after global [3–11] and local [12–20] quantum quenches has been the subject of intense theoretical interest. Often hard to pursue by analytical methods, many studies have become feasible in 1D by numerical methods [21, 22] based on Matrix Product State (MPS) [23, 24], and also by tensor network approaches [25].

If the initial state is prepared within a *finite* system, boundary effects such as Friedel oscillations interfere with a passing signal. System boundaries also limit the time span for tracing the signal, before it is reflected at the boundaries in a non-trivial manner. The maximum time is even more severely restricted by entanglement which develops across the system and which requires a computational effort that can drastically increase with time [26]. This has greatly hampered the analysis of large time asymptotic behavior [8, 9, 27, 38]. Boundary effects do not appear in *infinite* systems, for which the ground state and its time evolution can be calculated with MPS methods [28–31]. However, these methods require complete translational invariance and can therefore not be applied to study signal propagation.

In this letter we present a method to simulate the propagation of local signals on an infinite chain using MPS time evolution, without any finite size effects distorting the signal front. We study the time evolution of the Transverse Field Ising (TFI) model [3–7, 12, 13, 32–37] and of the XXZ spin $\frac{1}{2}$ chain [8–11, 14–17, 38] after a local quantum quench up to large times. We find distinct magnetization plateaus [18, 38], reminiscent of the plateaus observed in equilibrium frustrated spin chains

as a function of magnetic field [39–46]. In our case the plateaus develop over time in the longitudinal magnetization close to the signal front. Their heights and positions scale algebraically with time in the TFI model to high precision.

For our method we consider a general spin chain of infinite size, with finite range interactions, initially prepared in a state, such as the ground state, which is translationally invariant for sites $x > x_0$ to the right of some site x_0 . At time zero, the system is excited by a quantum quench like one or more spin flips at sites $x \leq x_0$ or a modification of the Hamiltonian at $x \leq x_0$. For finite range interactions it is known from the Lieb-Robinson bound [47] that wave fronts generated by such quenches can only propagate with a characteristic maximum velocity $v_{\max}$, i.e. within a “light cone” even in a non-relativistic system, as recently also seen experimentally [1]. Any correlations beyond the light cone are exponentially suppressed at increasing distance with a length scale of at most the correlation length [47].

We divide the system into three parts, namely the *co-moving window* (CMW) which moves towards the right with the wave front, and two half-infinite regions, a uniform one in front (i.e. to the right) of the window, and an arbitrary one to the rear. The window is chosen wide enough to contain the complete signal front, including the exponentially damped part to the right of the main front, to high precision. The signal will therefore not affect the system to the right of the window. Likewise, when the window moves with $v_{\max}$, modifications in the rear part will not affect the CMW and need not be calculated. Since bipartite entanglement [48–50] spreads at most with $v_{\max}$, the bipartite entanglement entropy is significantly lower around the wave front than in the bulk, allowing for low computational effort when using the CMW.

We label the sites according to the division we have introduced: left side $j \leq \ell$, CMW $\ell + 1 \leq j \leq r$, and right side $j \geq r + 1$. We consider a Hamiltonian with near-

Figure 1: (color online) Time evolution of magnetizations $\langle \hat{S}_x(t) \rangle$ and $\langle \hat{S}_z(t) \rangle$ of the TFI in a Comoving Window after a Jordan-Wigner excitation, at $h = 0.45$. Inset: Time evolution after a single spin flip of S^x without window movement. Color scale spans the data, from 0.074 (blue) to 0.4063 (red).

est neighbor couplings $\hat{H} = \sum_j \hat{h}_{j,j+1}$, which subdivides correspondingly into

$$\hat{H} = \hat{H}_L + \hat{h}_{\ell,\ell+1} + \hat{H}_M + \hat{h}_{r,r+1} + \hat{H}_R. \quad (1)$$

The wave function in the s^z basis becomes

$$\Psi(\dots s_{\ell-1} s_{\ell} | s_{\ell+1} s_{\ell+2} \dots s_r | s_{r+1} s_{r+2} \dots; t). \quad (2)$$

where s_j labels the spin at site j . It can be approximated very closely in the form of an infinite matrix product [23]

$$\dots L^{s_{\ell-1}} L^{s_{\ell}} A^{s_{\ell+1}} \dots A^{s_k} \lambda^k B^{s_{k+1}} \dots B^{s_r} R^{s_{r+1}} R^{s_{r+2}} \dots, \quad (3)$$

where $L^{s_j \leq \ell}$ are left-orthogonal matrices in the left part, $A^{s_{\ell+1} \leq j \leq r}$ and $B^{s_{\ell+1} \leq j \leq r}$ are left- and right-orthogonal matrices inside the CMW, respectively, $R^{s_{r+1} \leq j}$ are right-orthogonal matrices in the right part and $\lambda^{\ell \leq k \leq r}$ are diagonal matrices containing the Schmidt values of a bipartition at bond $(k, k+1)$. For a finite system, the left and right ends of (3) are terminated by contractions with boundary vectors; we however consider the infinite size limit. In standard TEBD notation [22], $L^{s_j} = \lambda^{j-1} \Gamma^{s_j}$, $A^{s_j} = \lambda^{j-1} \Gamma^{s_j}$, $B^{s_j} = \Gamma^{s_j} \lambda^j$, and $R^{s_j} = \Gamma^{s_j} \lambda^j$. The matrices R^{s_j} are obtained as the stationary state of iTEBD[28], thus there are only two independent matrices, and $R^{s_{j+2}} = R^{s_j}$.

Let us consider one step of the time evolution. Using Suzuki-Trotter decomposition [51], we apply adaptive time evolution with respect to $\hat{H}_M + \hat{h}_{r,r+1} + \hat{H}_R$ inside and to the right of the CMW, and, e.g., non-adaptive time evolution with respect to $\hat{H}_L + \hat{h}_{\ell,\ell+1}$ to the left of the CMW.

Adaptive time evolution inside the CMW can be performed either by tDMRG [21] or TEBD [22], using local operators $\hat{u}_{j,j+1}(\tau) = e^{-i\tau \hat{h}_{j,j+1}}$ with finite time steps τ . To the right side of the CMW, the evolution of $R^{s_{r+1}} R^{s_{r+2}} \dots$ is performed by iTEBD [28, 52].

Special attention has to be paid to the operation of $\hat{u}_{r,r+1}(\tau)$ at the junction between the CMW and the right

Figure 2: (color online) Magnetization $\langle \hat{S}_x(t) \rangle$ at times $190 < t < 500$, showing magnetization plateaus. Inset: $\langle \hat{S}_z(t) \rangle$ (red crosses) vs. position inside the window at $t = 100$ (lower line) and $t = 300$ together with the exact solution (blue circles, coinciding with data).

side. We explain our procedure in terms of tDMRG representations. After a sweeping process [21] to the right boundary of the CMW ($j = r$), and the first iTEBD half-step (on $\Gamma^{s_{r+1}} \lambda^{r+1} \Gamma^{s_{r+2}}$), we face the following matrix product

$$\dots A^{s_{\ell+1}} A^{s_{\ell+2}} \dots A^{s_r} \lambda^r R^{s_{r+1}} R^{s_{r+2}} \dots \quad (4)$$

We then operate with $\hat{u}_{r,r+1}(\tau)$ on $\psi^{s_r s_{r+1}} = A^{s_r} \lambda^r R^{s_{r+1}}$ and apply singular value decomposition (SVD including truncation) on the result, which yields

$$A^{s_{\ell+1}} A^{s_{\ell+2}} \dots A^{s_{r-1}} U^{s_r} \omega^r V^{s_{r+1}} R^{s_{r+2}} \dots, \quad (5)$$

with ω^r containing the updated Schmidt values.

After the second iTEBD half-step (on $\Gamma^{s_{r+2}} \lambda^{r+2} \Gamma^{s_{r+1}}$), the matrix $V^{s_{r+1}}$ will differ from the new matrix $R^{s_{r+1}}$ by some unitary MPS gauge transformation x , such that $V^{s_{r+1}} = x R^{s_{r+1}}$, since there is negligible influence of the signal around the right boundary by construction (see also results below). Using right orthogonality [23] $\sum_s R^s R^{s\dagger} = \mathbb{1}$, x is obtained as $x = \sum_{s_{r+1}} V^{s_{r+1}} R^{s_{r+1}\dagger}$. We arrive at

$$A^{s_{\ell+1}} A^{s_{\ell+2}} \dots A^{s_{r-1}} U^{s_r} \omega^r x R^{s_{r+1}} R^{s_{r+2}} \dots, \quad (6)$$

where the right side is again purely represented by matrices R^{s_j} . Regular tDMRG can now be continued by forming $\psi^{s_{r-1} s_r} = A^{s_{r-1}} U^{s_r} \omega^r x$ and sweeping back to the left of the CMW, which completes one time step of the adaptive update. Note that this protocol can also be performed using TEBD.

Non-adaptive time evolution to the left of the CMW can be performed similar to ref. 53. Consider $\hat{H}_L$ initially in a renormalized form $\hat{H}_L^{\text{eff}}$ with respect to the MPS matrices L^{s_j} , obtained, e.g., from an initial DMRG calculation [29, 30]. The matrix H_L^{eff} is thus defined in a basis $\{|a_\ell\rangle\}$ of the auxiliary space connecting L^{s_ℓ} and $A^{s_{\ell+1}}$. We include $h_{\ell,\ell+1}$ in DMRG fashion to form $H_{L,\ell+1} = H_L^{\text{eff}} + h_{\ell,\ell+1}$ in the block spin basis $\{|a_\ell s_{\ell+1}\rangle\}$.

Figure 3: (color online) Scaling of $\langle \hat{S}_x^x(t) \rangle$ vs. $(x - x_0)/t$. Insets: Algebraic scaling fits (blue lines) for the first (1) and second (2) magnetization plateau (red crosses). Left inset: position, right inset: height $\langle \hat{S}_x^x \rangle$.

$A^{s_{\ell+1}}$ is now updated by $U^{L,\ell+1}(\tau) = \exp(-i\tau \hat{H}_{L,\ell+1})$ to get

$$\tilde{A}_{a_{\ell}a_{\ell+1}}^{s_{\ell+1}} = \sum_{s'_{\ell+1}a'_{\ell}} U(\tau)_{(s_{\ell+1}a_{\ell})(s'_{\ell+1}a'_{\ell})}^{L,\ell+1} A_{a'_{\ell}a_{\ell+1}}^{s'_{\ell+1}}. \quad (7)$$

This update is non-adaptive because possible changes of the matrices L^{s_j} are compressed to $A^{s_{\ell+1}}$. The CMW however, when moving with v_{max} , will not be affected. The non-adaptive update can also be done by means of the renormalized imaginary-time transfer matrix, as in finite-temperature DMRG [54]. An adaptive update with gauge transformation could be used as well, when the initial state is translationally invariant to the left. An even simpler alternative is to set $\hat{h}_{l,l+1} = 0$, disconnecting the left part, with similar results.

The window is moved by v_{max} when known beforehand, or the movement is triggered by the change of some local observable or the bipartite entanglement at a sufficient distance from the right boundary. A shift of the CMW is done by including $R^{s_{r+1}}$ as a new rightmost matrix into the CMW, and by absorbing the leftmost matrix $A^{s_{\ell+1}}$ into the left side by using it to renormalize $H_{L,\ell+1}^{eff}$. Similar operations apply for an alternative shift by a whole iTEBD unit cell.

Results. The spin- $\frac{1}{2}$ Transverse Field Ising model [4, 5, 7, 13, 32–37] on an infinite chain defined by $\hat{H} = -\sum_j \hat{S}_j^x \hat{S}_{j+1}^x - h \sum_j \hat{S}_j^z$ can be diagonalized exactly [55, 56] by means of a Jordan-Wigner (JW) transformation [57], but the time evolution of observables is in general very expensive to calculate [33]. At $h < h_c = 0.5$ there is long range order in $\hat{S}^x$. We prepared the system in the symmetry broken ground state $|0\rangle$ with $\langle \hat{S}_j^x \rangle > 0$ using iDMRG [29, 30]. As a local quantum quench we employed an initial JW excitation $(c_{x_0}^\dagger + c_{x_0})|0\rangle = \prod_{i < x_0} (-2\hat{S}_i^z) (\hat{S}_{x_0}^+ + \hat{S}_{x_0}^-)|0\rangle$ at site x_0 inside the window, where $c^\dagger, c$ are JW fermion creation and annihilation operators [57]. It corresponds to a spin flip in z -direction at site x_0 and a domain wall in x -direction be-

tween sites $x_0 - 1$ and x_0 . We present data at $h = 0.45$, using $\tau = 0.002$ and maximum matrix size 26.

The time evolution inside the CMW (Fig. 1) shows that boundary effects are indeed removed at both ends of the CMW. Window movement was triggered by entanglement, resulting in a window velocity of $0.455(4)$, equal to the maximum group velocity $v_{max} = h$ of the TFI [3]. When the window is not moved (Fig. 1, inset), an impinging signal is absorbed by both boundaries temporarily, though reflections occur eventually. The entanglement entropy (not displayed) shows reflections at about $t = 70$ at both boundaries.

The agreement of the transverse magnetization in Fig. 2(inset) with exact results which we calculated for the JW excitation is excellent, even at very large times, with relative deviations of less than $\mathcal{O}(10^{-4})$ beyond the rear boundary. The transverse magnetization develops two shallow domain walls after the quench, with an overall scaling $\langle \hat{S}_\infty^z - \hat{S}_j^z(t) \rangle \sim 1/t$ away from the signal front, as expected [33, 58]. Close to the front, there are oscillations. The difference of the ground state magnetization and the first minimum numerically fits a power law $\sim t^{-1.127(8)} \simeq t^{-9/8}$.

For the *longitudinal* magnetization $\langle \hat{S}_x^x(t) \rangle$, analytical calculations are much more difficult, and results have been available in the literature only very recently [3]. We find that shoulders appear during the time evolution, which develop into distinct magnetization plateaus, with a relative variation in $\langle \hat{S}_x^x(t) \rangle$ of less than 0.1% over 4 sites for the rightmost plateau in Fig. 2. The plateaus slowly widen over time. Analogous steps have previously been observed in the XX chain [18], and with $\langle \hat{S}^z \rangle$ in the *paramagnetic* phase of the TFI at $h = 5$ [35]. Fig. 3 shows that the magnetizations at different times can be scaled to a single function $\langle \hat{S}_x^x(t) \rangle = f((x - x_0)/t)$ away from the front, similar to the behavior of $\langle \hat{S}_x^z(t) \rangle$ in Ref. 35. The plateaus close to the signal front are excellently described by a power law $\langle \hat{S}_x^x(t) \rangle = m + at^b$, where $m = 0.4026(2)$, $b = -0.3497(6)$ for the first plateau and $m = 0.3982(4)$, $b = -0.362(1)$ for the second one, with $m = 0.406269$ for the ground state. Their positions p obey $(p - x_0)/t = v - ct^d$ with $v = 0.4500(3)$, $c = 1.52(2)$, $d = -0.675(4)$, resp. $v = 0.4503(4)$, $c = 2.51(3)$, $d = -0.666(4)$. The exponents d are very close to $-2/3$. We note that the velocities $(p - j)/t$ converge to $v = h = v_{max}$ to high precision making the slope in Fig. 3(left inset) sharper for larger times. The line of crossing points visible in the figure at large $\langle \hat{S}^x \rangle$ thus also converges to $v = h$. However, since $d > -1$, the positions of the plateaus move *away* from the signal front with a power law $\sim t^{d+1} \approx t^{1/3}$. The exponents are virtually unchanged within error bars for different fields $h = 0.2, 0.3, 0.4 < h_c$ (see also [33]) and for a different quench without the local $\hat{S}^z$ flip.

Finally, we investigated the XXZ antiferromagnet [8–10, 15–17, 38], $\hat{H} = -J^{xy} \sum_j (\hat{S}_j^x \hat{S}_{j+1}^x + \hat{S}_j^y \hat{S}_{j+1}^y) -$

Figure 4: (color online) Time evolution of the bipartite entanglement entropy and of $\langle (-1)^j S_j^z \rangle$ in the XXZ antiferromagnet after a local spin flip at $J^{xy} = 1$ and $J^z = -3$.

Figure 5: (color online) Magnetization $\langle (-1)^j S_j^z \rangle$ in the XXZ model at times $20 < t < 200$, showing developing plateaus. Inset: data plotted vs. position inside the CMW, for times $t > 60$, with the last 2 plateaus.

$J^z \sum_j \hat{S}_j^z \hat{S}_{j+1}^z$, using $\tau = 0.01$ and matrix dimension 100. We prepared the system in the symmetry broken infinite size ground state at $J^{xy} = 1, J^z = -3$, with $(-1)^j \langle \hat{S}_j^z \rangle > 0$. At time 0 we flipped a spin at site x_0 , thereby producing two domain walls (spinons). During the time evolution, these domain walls spread in opposite directions (Fig. 4), forming a widening region with negative $(-1)^j \langle \hat{S}_j^z \rangle$ in between. We find $v_{max} = 1.945(2)$ from the evolution of $\langle \hat{S}^z \rangle$. Close to the initial excitation, the bipartite entanglement starts to grow considerably but within the CMW it stays small at later times. At large times t , distinct magnetization plateaus develop again, as shown in Fig. 5, with a relative variation of less than 0.1% over 6 sites for the rightmost plateau in the figure. Over time, they widen and move away slowly from the signal front (Fig. 5, inset). The plateaus do not follow power laws similar to the TFI. The scaling behavior in the XXZ model [8, 9] is currently under investigation.

Conclusions. We have introduced a comoving window, employing an easy-to-implement gauge transformation in order to connect the CMW to its surroundings. We have shown that the CMW can follow the propagation of a signal front on an infinite size system unimpeded for very long simulation times. We note that even

when the window is not moved, local signals can be simulated on the background of an infinite system, without perturbations which would otherwise emanate from the boundary. In this case the signal is temporarily absorbed by the boundary, though simulation times are eventually limited by the size of the window.

The CMW method is not restricted to evolution of excitations under uniform Hamiltonians. For example, the AKLT model [59] with inhomogeneous bond interactions or 1D quantum systems under exponential or hyperbolic deformation [60, 61] have uniform ground states, whereas the Hamiltonian is not uniform.

The CMW enabled us to calculate the relaxation after local quantum quenches in the Transverse Field Ising (TFI) model and in the XXZ antiferromagnet with low computational cost up to very large times. We have found distinct dynamical magnetization plateaus close to the signal front in both models. Their scaling is algebraic and well described in the TFI, whereas in the XXZ model it is more complicated and under current investigation.

Note added. During the preparation of this letter we learned that work on related approaches was being completed by two other groups [62, 63].
